IR spectra of phenol–CH$_4$ complexes generated in a supersonic expansion were measured before and after photoionization. The IR spectrum before ionization shows the free OH stretching vibration ($\nu_{OH}$) and the structure of neutral phenol–CH$_4$ in the electronic ground state ($S_0$) is assigned to a $\pi$-bound geometry, in which the CH$_4$ ligand is located above the phenol ring. The IR spectrum after ionization to the cationic ground state ($D_0$) exhibits a red shifted $\nu_{OH}$ band assigned to a hydrogen-bonded cationic structure, in which the CH$_4$ ligand binds to the phenolic OH group. In contrast to phenol–Ar/Kr, the observed ionization-induced $\pi \rightarrow H$ migration has unity yield for CH$_4$. This difference is attributed to intracluster vibrational energy redistribution processes.

1. Introduction

Noncovalent interactions, such as hydrogen bonds (H-bonds) and van der Waals interactions ($\pi$-stacking), are responsible for a large number of phenomena in chemistry, biology, and their related research fields.$^{1-3}$ Advanced quantum chemical calculations have proven that van der Waals interactions, particularly those generated by aromatic rings, are of comparable strength to H-bonds.$^3$ Thus, their competition controls the structure, dynamics, and function of supramolecular systems such as DNA. Phenol (PhOH) and its van der Waals complexes with rare gas (Rg) or simple molecular ligands are benchmark systems to understand the competition between $\pi$-stacking and H-bonding, because they are the smallest molecular systems featuring both $\pi$-stacking to the aromatic ring and H-bonding to the OH group.$^{4-18}$

The structures of PhOH–Rg$_n$ complexes have been studied extensively. In the neutral ground state ($S_0$), analyses of intermolecular vibrations in $S_1$–$S_0$ excitation spectra, high resolution UV spectra, and infrared (IR) dip spectra demonstrated a $\pi$-bound structure for PhOH–Rg (Rg = Ar and Kr), in which the Rg ligand binds above the benzene ring by $\pi$-stacking interactions, denoted as (10).$^{4,5,7,18,22}$ The notation ($pq$) indicates PhOH–Rg$_n$ structures in which $p$ and $q$ $\pi$-bonded Rg ligands are located above and below the aromatic ring, respectively. For larger PhOH–Ar$_n$ clusters ($n = 2$ to $4$), IR dip spectra revealed that all of them have $\pi$-bound structural motifs in $S_0$, but various isomers can coexist, such as (11) and (20) for $n = 2$, (21) and (30) for $n = 3$, and (31) for $n = 4$.$^{27,30}$ Recently, high-level quantum chemical calculations indicated that the $\pi$-bound PhOH–Ar structure is a global minimum in the neutral ground state, while the H-bound structure was found to be a transition state or at most a shallow local minimum.$^{16,20,21,30}$ All the isomers can readily be separated by their different $S_1$–$S_0$ electronic transitions, enabling isomer selective excitation and ionization.$^{27,30}$

Structural studies of PhOH$^+$–Rg cations in their cationic ground state ($D_0$) were performed using photoionization efficiency, mass-analyzed threshold ionization, and zero-kinetic-energy photoelectron spectroscopy.$^{4,8-10,14,23,24,26}$ These spectroscopic studies suggested a $\pi$-bound structure for PhOH$^+$–Rg dimers (Rg = Ar, Kr, and Xe) in the $D_0$ states. Early IR dip spectra also supported a $\pi$-bound structure, because almost no shift of the OH stretching vibration ($\nu_{OH}$) was observed upon complex formation.$^7$ However, IR photodissociation spectra of PhOH$^+$–Ar/Kr generated in an electron impact (EI) ion source showed that the most stable isomer in the $D_0$ state is in fact the H-bound form.$^{11-13,19}$ Using photoionization, only the $\pi$-bound structure can directly be populated according to the Franck–Condon principle. On the other hand, EI does not have such a restriction and produces the most stable H-bonded structure.$^{32}$ In this ion source, the first step of the reaction is EI ionization of the phenol...
monomer, which is followed by three-body aggregation forming the PhOH$^{-}$Rg cluster predominantly in its most stable H-bonded structure.\textsuperscript{13}

The structural restriction in photoionization given by the Franck–Condon principle has opened a new research direction in the study of dynamical processes of noncovalent interactions.\textsuperscript{31} The $\pi$-bound structures in PhOH$^{-}$Rg\textsubscript{0} generated by photoionization are a metastable state in D\textsubscript{0} and isomerization toward the H-bound global minima is possible. This photoionization induced $\pi \rightarrow H$ site switching reaction was observed for PhOH–Kr, the (11) isomer of PhOH–Ar\textsubscript{2}, and the (30) isomer of PhOH–Ar\textsubscript{3} using nanosecond ("static") and picosecond (time-resolved) UV-UV-IR dip spectroscopy.\textsuperscript{15,17,19,27,29} In nanosecond spectroscopy, the IR dip spectra of PhOH$^{-}$Rg\textsubscript{0} show the H-bonded $\nu_{OH}$ vibration for the photoionized complexes (in D\textsubscript{0}), although all of them are assigned to $\pi$-bound structures in S\textsubscript{0}.\textsuperscript{17,19,27,29} The picosecond time-resolved UV-UV-IR spectra demonstrate the formation and subsequent decay of the free $\nu_{OH}$ band of the $\pi$-bound complexes as a function of the delay time from the ionization event, with timescales of the order of 1–100 picoseconds.\textsuperscript{15,17,27,28,31} Simultaneously, a gradual growth of the bound $\nu_{OH}$ band of the H-bonded complex is observed. Thus, picosecond time-resolved IR spectroscopy clearly elucidates the formation of the metastable $\pi$-bound cation and its $\pi \rightarrow H$ switching reaction in real time.\textsuperscript{31} This $\pi \rightarrow H$ switching reaction is induced by the sudden change of the phenol–ligand interaction upon photoionization. In this respect, PhOH$^{-}$Rg\textsubscript{0} clusters can also serve as a molecular model system to probe solvation dynamics. Similar molecular migration reactions in clusters have recently been observed for water moving around a peptide linkage in the acetanilide–water dimer and for related molecular complexes with polar ligands.\textsuperscript{32,39–49}

In these solvent migration events, the reaction yield is one of the important parameters for understanding their mechanism. For example, the IR spectrum of PhOH$^{-}$Kr recorded after photoionization shows both the free and the H-bonded $\nu_{OH}$ vibrations even for nanosecond delays after ionization.\textsuperscript{19,28,29} Similar results were observed for PhOH$^{-}$Ar.\textsuperscript{17,27} Thus, it has been concluded that the initially generated $\pi$-bound PhOH$^{-}$Rg isomer isomerizes towards the H-bound isomer, but the H $\rightarrow \pi$ back reaction also takes place, and finally both species coexist in equilibrium. As a result, the $\pi \rightarrow H$ switching reaction yield in PhOH$^{-}$Rg is less than unity. On the other hand, nanosecond IR spectra of PhOH–Ar\textsubscript{2} and PhOH–Ar\textsubscript{3} detect only H-bound species long after photoionization, indicating that the $\pi \rightarrow H$ reaction yield is unity.\textsuperscript{15,17,27} This significant difference in the yield can be understood by the presence of a second (and further) Rg ligand(s) in the larger PhOH$^{-}$Rg\textsubscript{n} complexes with $n \geq 2$. The second ligand can remain at the original $\pi$-binding site after the $\pi \rightarrow H$ site switching of the first ligand. Its three intermolecular vibrational modes act as a bath for the switching reaction. As a result, the H-bound reaction product can immediately be stabilized by intracluster vibrational energy redistribution (IVR). IVR prevents the H $\rightarrow \pi$ back reaction to the $\pi$-bound structure leading to a 100% reaction yield for the $\pi \rightarrow H$ forward reaction. As the PhOH–Rg dimers do not have a second ligand, which can prevent the back reaction, the isomerization yield is non-unity.\textsuperscript{31}

However, recent results on water migration from the CO to the NH site in the acetanilide$^{-}$water and related dimers show 100% reaction yields although the complex does not have a second ligand,\textsuperscript{19–41} indicating that a refined explanation for the yield is required. Actually, the H$_{2}$O ligand has internal structure giving rise to more intermolecular degrees of freedom compared to the Rg complexes. To this end, we investigate here the complex of PhOH, the molecular benchmark for $\pi \rightarrow H$ site switching, with a CH$_{4}$ ligand. Similar to Rg ligands, CH$_{4}$ interacts with neutral and ionic phenol mainly via its polarizability. Thus, the topologies of the potential energy surfaces of PhOH–CH$_{4}$ and PhOH–Rg are expected to be similar in both charge states.\textsuperscript{13}

However, CH$_{4}$ has internal structure and is not spherical like Rg atoms, which can influence the reaction dynamics and the reaction yield. With this motivation, we have measured IR spectra of PhOH–CH$_{4}$ in S\textsubscript{0} and D\textsubscript{0}. From the IR spectra before and after ionization, we will explore the photoionization-induced $\pi \rightarrow H$ site switching reaction and discuss its yield in terms of IVR. The only spectral information available for PhOH–CH$_{4}$, namely the complexation-induced red shifts in the S\textsubscript{1} and ionization energies\textsuperscript{34} and Raman spectra of PhOH–CH$_{4}$ in the fingerprint range\textsuperscript{35} are consistent with a $\pi$-bound geometry in S\textsubscript{0}. In contrast, IR spectra of PhOH$^{-}$–(CH$_{4}$)$_{n}$ generated in the EI source prove that the H-bound structure is the global minimum in the cationic D\textsubscript{0} state.\textsuperscript{13} Thus, it was anticipated that $\pi \rightarrow H$ isomerization of PhOH$^{-}$–CH$_{4}$ could be detected in the current study by photoionization of PhOH–CH$_{4}$ complexes generated in a molecular beam.

2. Experimental and computational techniques

The setup for IR dip spectroscopy has been described previously.\textsuperscript{50} PhOH purchased from SIGMA-ALDRICH was used after purification by vacuum sublimation. The sample vapor was diluted at room temperature in a gas mixture of $\sim$10% CH$_{4}$ in He at 3 bar. The resulting mixture was expanded into a vacuum chamber (typically 2 $\times$ 10$^{-5}$ Torr) using a pulsed nozzle to produce PhOH–CH$_{4}$ clusters in a supersonic jet. The clusters were ionized by two-colour two-photon resonance-enhanced multiphoton ionization (REMPI) using two tunable UV lasers generating $\nu_1$ and $\nu_2$. Here, PhOH–CH$_{4}$ was pumped to the S\textsubscript{1} origin by $\nu_1$ and subsequently ionized by $\nu_2$. Two-colour soft ionization keeps the excess energy after ionization small and prevents dissociation. The produced cluster ions were guided into a quadrupole mass filter and detected by a channel multiplier. The ion signal was digitized by a digital boxcar integrator after amplification and recorded in a personal computer as a function of the laser frequency. The UV photons $\nu_1$ and $\nu_2$ were generated by frequency-doubled outputs of dye lasers pumped by nanosecond Nd:YAG lasers. Tunable IR light ($\nu_{IR}$) was generated by difference frequency generation in a LiNbO$_3$ crystal between the second harmonic of a Nd:YAG laser and the output of a dye laser. The UV

and $\nu_{\text{IR}}$ laser beams were focused on the molecular beam in a coaxial and counter-propagating geometry using lenses with $f = 400$ mm. The experiment was operated at 10 Hz. IR spectra in S$_0$ were obtained using IR dip spectroscopy. To this end, clusters were first irradiated with $\nu_{\text{IR}}$, and after a 50 ns delay with $\nu_1$ and $\nu_2$. While monitoring the ion signal of PhOH$^+$–CH$_4$, $\nu_{\text{IR}}$ was scanned through the OH stretching region. When $\nu_{\text{IR}}$ is resonant with a vibrational level, the population of the vibrational ground state decreases, and the ion signal is reduced (IR dip). Thus, the IR spectrum in S$_0$ was measured as a depletion of the ion signal. The IR spectra in D$_0$ were measured for two different ionization processes, namely photo-ionization (REMPI) and electron-impact ionization (EI). For the IR spectrum after REMPI (briefly REMPI-IR), the same setup as described above was used. In this case, $\nu_{\text{IR}}$ was introduced 50 ns after $\nu_1$ and $\nu_2$. Vibrational excitation of PhOH$^+$–CH$_4$ causes vibrational predissociation of the cluster, and the IR spectrum was obtained by monitoring the depletion of the parent mass signal. The IR spectrum of PhOH$^+$–CH$_4$ generated by EI was obtained in a tandem quadrupole mass spectrometer coupled with an electron impact ionization (EI) source and an octopole ion trap, as described elsewhere.$^{13,31,32,51}$ The EI-IR spectrum exhibits the vibrational transitions of the most stable structure of the cold cation complexes and provides a reference OH stretching frequency ($\nu_{\text{OH}}$) for the structural assignments in the D$_0$ state.

$Ab$ initio quantum chemical calculations were carried out using the Gaussian09 program$^{52}$ to obtain stable structures, theoretical IR spectra, and binding energies of PhOH$^+$–CH$_4$ (Table 1). Geometry optimization was performed at the MP2/aug-cc-pVDZ level, and normal mode analysis of the stationary points confirmed their nature as minima and was used to predict their IR spectra. Harmonic vibrational frequencies were scaled by factors of 0.9605 and 0.9509 for the neutral and the cationic species, respectively, to reproduce the $\nu_{\text{OH}}$ frequencies of PhOH$^+$ in the respective charge states (3657 and 3534 cm$^{-1}$).$^{7,37,53}$ The binding energy of the cluster was estimated from single-point calculations on the minima at the MP2/aug-cc-pVTZ level, including basis set super-position error (BSSE) corrections and harmonic zero-point vibrational energy (ZPE) corrections obtained using the aug-cc-pVDZ basis. As spin contamination at the MP2 level is severe for the PhOH$^+$ cation,$^{10}$ additional calculations have been performed at the M06-2X/aug-cc-pVTZ level (Table 1). As will be shown below, the intermolecular binding energies obtained at the M06-2X level are systematically larger than those at the MP2 level and match better with the available experimental data.

3. Results and discussion

To the best of our knowledge, the S$_1$–S$_0$ electronic spectrum of PhOH–CH$_4$ has not been reported except for the frequency of the S$_1$ origin.$^{33,34}$ Fig. 1 shows the S$_1$–S$_0$ REMPI spectrum of PhOH–CH$_4$ obtained in a supersonic jet in the present work. The strongest transition at 36 290 cm$^{-1}$ is red shifted by $\Delta S_1 = -59$ cm$^{-1}$ from the S$_1$ origin of bare PhOH. The band position is slightly lower in energy than those reported previously (36 302$^3$, 36 298 cm$^{-1}$ (ref. 34)), while the shift matches closely ($\Delta S_1 = -58$ cm$^{-1}$). Several low-frequency transitions appearing above the S$_1$ origin are attributed to intermolecular vibrations by comparison to the similar spectra of benzene–CH$_4$,$^{54}$ toluene–CH$_4$,$^{55}$ and aniline–CH$_4$.$^{56-59}$ To measure IR dip spectra in S$_0$, $\nu_1$ was fixed to the S$_1$ origin, while $\nu_2$ was tuned to 32 140 cm$^{-1}$. Fig. 2 shows the IR dip spectra of (a) PhOH and (b) PhOH–CH$_4$ in S$_0$, respectively. The free $\nu_{\text{OH}}$ band of PhOH at 3657 cm$^{-1}$ is consistent with the previous report.$^{60}$ The IR dip spectrum of the PhOH–CH$_4$ complex shows a sharp vibrational
transition at 3656 cm\(^{-1}\), which is readily assigned to \(\nu_{\text{OH}}\) of PhOH in the complex. Since \(\nu_{\text{OH}}\) is essentially unchanged by complex formation with CH\(_4\), the complex is concluded to have a \(\pi\)-bound structure, in which CH\(_4\) is located above the benzene ring. Similar \(\pi\)-bound structures were found for PhOH–Ar\(_n\) \((n = 1\) and 2\),\(^{25} \text{ PhOH–Kr,}^{5,7} \text{ aniline–Ar,}^{58,61} \text{ and 4-aminobenzonitrile–Ar}^{62}\) in S\(_0\). The MP2 and M06-2X calculations support this assignment as they predict the \(\pi\)-bound isomer to be significantly more stable than the H-bound one, \(D_0(\pi) = 388 \text{ cm}^{-1}\) and \(D_0(\text{OH}) = 262 \text{ cm}^{-1}\) at the M06-2X level (Table 1). Moreover, the predicted red shift of \(\Delta\nu_{\text{OH}} = -4 \text{ cm}^{-1}\) for H-bound PhOH–CH\(_4\) is not compatible with the measured IR spectrum. The reported Raman spectrum of PhOH–CH\(_4\) is also inconsistent with a H-bounded structure in terms of complexation-induced frequency shifts and line widths.\(^{33}\) Finally, the intermolecular structure of the S\(_1\)–S\(_0\) spectrum of PhOH–CH\(_4\) is quite similar to that of benzene–CH\(_4\) and toluene–CH\(_4\),\(^{34,55}\) both of which cannot have H-bounded structures. Thus, all spectral and quantum chemical evidence is consistent with a \(\pi\)-bound equilibrium structure of PhOH–CH\(_4\) in S\(_0\).

Fig. 3(a) shows the REMPI-IR spectrum of PhOH\(^+\)–CH\(_4\) in the \(\nu_{\text{OH}}\) region. A broad and intense vibrational transition was observed at \(\sim 3390 \text{ cm}^{-1}\). Significantly, no transition was found in the vicinity of \(\nu_{\text{OH}}\) of bare PhOH\(^+\) at 3534 cm\(^{-1}\) (ref. 53 and 63) indicated by a dashed line. Thus, we assign the broad band to \(\nu_{\text{OH}}\) of the cationic complex. The red shift and broadening of \(\nu_{\text{OH}}\) is a clear signature of the formation of a H-bond. In fact, such a large red shift of \(\Delta\nu_{\text{OH}} \sim -144 \text{ cm}^{-1}\) is only reproducible by the H-bound isomer as shown by the theoretical IR spectra in Fig. 3(c) and (d). Therefore, it is concluded that PhOH\(^+\)–CH\(_4\) generated by photoionization has an H-bonded structure in which CH\(_4\) binds to the OH group. The EI-IR spectrum of cold PhOH\(^+\)–CH\(_4\) shown in Fig. 3(b) arises from the global minimum of the cation cluster and confirms this assignment.\(^{13}\) The H-bonded \(\nu_{\text{OH}}\) transition is found at 3365 cm\(^{-1}\), which is consistent with the predicted value of 3423 cm\(^{-1}\) (MP2 level). The red shift predicted by the MP2 calculations is somewhat smaller than the experimental one \((\Delta\nu_{\text{OH}} = -111 \text{ and } -169 \text{ cm}^{-1}\)\), as they underestimate the interaction energy. For comparison, the red shift calculated at the M06-2X level \((\Delta\nu_{\text{OH}} = -136 \text{ cm}^{-1}\)\) is closer to the experimental value, indicating that this level provides a closer approximation to the true interaction energy. The \(\nu_{\text{OH}}\) frequency of cold H-bonded PhOH\(^+\)–CH\(_4\) clusters observed in the EI-IR spectrum corresponds to the red edge of the broad \(\nu_{\text{OH}}\) band observed in the REMPI-IR spectrum. This difference is rationalized by the different temperatures of PhOH\(^+\)–CH\(_4\) generated by EI and REMPI. For the EI-IR spectrum, PhOH\(^+\)–CH\(_4\) complexes were generated and cooled directly in the supersonic expansion. In the REMPI process, on the other hand, the complexes were ionized after the cooling process. The complexes are then under collision-free conditions, with the ionization excess energy remaining in the complexes. It is also known that H-bonded \(\nu_{\text{OH}}\) bands of hot clusters are blue shifted because H-bonds are weakened by excitation of intramolecular proton donor vibrations.\(^{13,31,32}\) Therefore, the observed spectral feature in the REMPI-IR spectrum of PhOH\(^+\)–CH\(_4\) arises from \(\nu_{\text{OH}}\) of “hot” H-bound dimers (vide infra).

The detection of the H-bound structure after photoionization indicates that CH\(_4\) migrates from the aromatic ring to the OH site in the cationic ground state, because the structure in S\(_0\) is \(\pi\)-bound and photoionization keeps the same structure due to the Franck–Condon principle. The migration may occur in S\(_1\); however, this scenario does not match the spectral features.
observed in the S1–S0 REMPI spectrum (Fig. 1). In the REMPI spectrum, the S1 origin is the strongest band and low frequency vibrations assigned to intermolecular modes are weak and without prominent progression. In addition, the S1–S0 excitation spectrum is very similar in appearance to that of benzene–CH4, which cannot exhibit any type of π → H isomerization. Thus, it is concluded that the structure remains π-bound also in S1, and the CH4 ligand switches the binding motif from π-bound to H-bound after photoionization in the D0 state.

Similar to PhOH–Ar2, the yield of the π → H isomerization reaction is 100% in the PhOH–CH4 dimer. In the (11) isomer of PhOH–Ar2, the two Ar atoms are bound to opposite sides of the benzene ring in S1. One of the Ar atoms migrates to the OH group after photoionization yielding the H-bound structure denoted as (H10). No vibrational signature of the doubly π-bound (11) structure was found long after ionization, i.e., the reaction yield for the ionization-induced π → H site switching is unity. In contrast, the similar π-bound PhOH–Kr dimer shows both H-bound and free νOH bands long after photoionization, with a finite equilibrium population between π-bound and H-bound structures. The reaction yield was evaluated as only ~40%. Interestingly, for the PhOH–CH4 dimer, no free νOH band was found in the REMPI-IR spectrum, and the π → H site switching yield is unity, similar to that in the PhOH–Ar2 trimer. Thus, although both PhOH–Kr and PhOH–CH4 have only a single ligand and both are probed under isolated collision-free conditions in a supersonic jet, the reaction yields are qualitatively different.

For the PhOH–Ar2 trimer, the 100% reaction yield was rationalized by the stabilization of the H-bound (H10) isomer via fast IVR. After the π → H site switching reaction, the H-bound complex has significant vibrational excess energy originating from the energy difference between the π-bound and the H-bound structures. In the H-bound (H10) trimer, the spectator Ar atom remains located on the π-ring, and thus its three intermolecular vibrations can act as bath modes and accept vibrational excess energy of the H-bound Ar atom. In this way, the vibrational excess energy in the reaction coordinate decreases significantly and the H → π back reaction is efficiently quenched.

On the other hand, the π ⇔ H equilibrium observed after photoionization of PhOH–Rg (Rg = Ar, Kr) dimers can be explained by the lack of bath modes. All three intermolecular modes in PhOH−Rg originating from the three translational degrees of freedom of the single Rg atom are required to describe the reaction coordinate for Rg isomerization. Just after the π → H site switching, the isomerization excess energy is localized in the reaction coordinate. However, no low frequency bath modes in the complex are available to accept the excess energy because all three intermolecular vibrational modes are already involved in the reaction coordinate and cannot act as bath modes for IVR. Therefore, the H → π back reaction can take place in accordance with the classical description, and finally the π ⇔ H equilibrium is achieved.

Similar to PhOH–Rg, the PhOH–CH4 dimer has a single spherical top ligand. The CH4 ligand, however, is not a sphere like a Rg atom but has internal structure and three rotational degrees of freedom. The PhOH–CH4 dimer has six intermolecular modes, three originating from translations and three from rotations. Analogous to the Rg case, the reaction coordinate for the CH4 site switching requires all three translational motions. As the coupling of the rotation-derived modes with the isomerization coordinate is weak, at least one of them can act as the bath mode for IVR. Those modes can accept the excess energy after the isomerization, stabilize the “hot” nascent H-bound complex by IVR and thus prevent the H → π back reaction. Therefore, the 100% reaction yield can be explained by fast IVR, mainly by coupling of the isomerization coordinates to the intermolecular vibrations related to the internal rotation of CH4.

Fig. 4 summarizes the reaction mechanism of the photoionization-induced π → H site switching reaction in PhOH−CH4 in a potential energy diagram. In the following, we combine the available experimental information with the data from the M06-2X calculations (Table 1) to derive a consistent quantitative picture of the energetics of this reaction potential because of the importance of energetics in the reaction. The binding energy of H-bound PhOH–CH4 predicted by the M06-X level (D0 = 1620 cm−1) is quite similar to that of the related H-bound PhOH–N2 complex precisely measured as 1640 ± 10 cm−1 by mass-analyzed threshold ionization spectroscopy. This similarity is expected, because both complexes exhibit the same complexation-induced red shifts ΔνOH = −169 cm−1. Moreover, similar H-bound energies for CH4 and N2 ligands are due to their similar proton affinities. Clearly, the binding energy derived for H-bound PhOH−CH4 at the MP2 level (D0 = 1129 cm−1) is too low and not consistent with the magnitude of the measured ΔνOH shift. Similarly, the binding energy predicted for the π-bound PhOH−CH4 isomer at the M06-2X level (D0 = 647 cm−1) is more realistic than that at the MP2 level (D0 = 494 cm−1) by comparison to experimental dissociation energies estimated from photodissociation data of PhOH−CH4.
CH4-containing complexes of aromatic ions.\(^{65,66}\) On the basis of the M06-2X calculations, the gain in internal energy upon \(\pi \rightarrow \text{H}\) isomerization is of the order of 1000 cm\(^{-1}\). Additionally, the initially prepared \(\pi\)-bound complex may already contain some amount of internal energy, which depends on the Franck–Condon factors for photoionization from the \(S_1\) origin and the ionization excess energy. The difference between the two-photon energy used for two-color soft ionization \((\nu_1 + \nu_2 = 36290 + 32140 = 68430 \text{ cm}^{-1})\) and the adiabatic ionization energy of \(\pi\)-bound PhOH\(^+\)–CH4 \((\text{IE} = 68334 \text{ cm}^{-1})^{14,67}\) indicates that the maximum internal energy available upon photoionization is around 100 cm\(^{-1}\). As a result, the barrier for \(\pi \rightarrow \text{H}\) isomerization in the \(D_0\) state of PhOH\(^+\)–CH4 must be relatively small. Moreover, the total internal energy of the H-bound PhOH\(^+\)–CH4 product after ionization is estimated as \(\sim 1050 \pm 100 \text{ cm}^{-1}\). Finally, we note that both the adiabatic IE and its complexation-induced red shift measured for \(\pi\)-bound PhOH\(^+\)–CH4 \((\text{IE} = 68334 \text{ cm}^{-1})\)\(^{14,67}\) are in good agreement with the predictions of the M06-2X calculations \((\text{IE} = 68064 \text{ cm}^{-1})\), confirming that this theoretical level indeed makes reliable predictions for the interaction between PhOH\(^+\) and CH4 in both charge states. In fact, \(\Delta\text{IE}\) corresponds to the difference of the binding energies of \(\pi\)-bound PhOH\(^+\)–CH4 in the \(S_0\) and \(D_0\) states.

4. Conclusions

In summary, IR spectra of the PhOH\(^+\)–CH4 dimer in the \(S_0\) and \(D_0\) states were recorded in the \(\nu_{\text{OH}}\) range using IR dip spectroscopy. While the neutral dimer has a \(\pi\)-bound structure in \(S_0\), the cation dimer has a H-bound structure in \(D_0\). From the Franck–Condon principle for photoionization, one can conclude that the CH4 ligand switches its binding motif from \(\pi\)-bonding above the aromatic ring to H-bonding at the OH site. The 100% reaction yield observed for this prototypical \(\pi \rightarrow \text{H}\) site switching triggered by ionization is explained by rapid IVR of the H-bound structure mainly due to the intermolecular energy transfer from the reaction coordinate to intermolecular modes originating from internal rotational degrees of freedom of CH4. Following aromatic complexes with atomic and nonpolar Rg ligands, and those with polar H2O and CH3OH ligands, PhOH\(^+\)–CH4 is the first CH4-containing complex for which the ionization-induced site-switching of the preferred binding motif is observed. Typical time scales for such site switching reactions are of the order of 1–100 ps.\(^{15,17,40}\) Future efforts will be aimed at the time-resolved investigation of this prototypical intermolecular isomerization reaction.\(^{15,17,27,31,40}\)
