Solar hydrogen evolution using metal-free photocatalytic polymeric carbon nitride/CuInS$_2$ composites as photocathodes

Florent Yang, Vadym Kuznietsov, Michael Lublow, Christoph Merschjann, Alexander Steigert, Joachim Klaer, Arne Thomas and Thomas Schedel-Niedrig

Polymeric carbon nitride (g-C$_3$N$_4$) films were synthesized on polycrystalline semiconductor CuInS$_2$ chalcopyrite thin film electrodes by thermal polycondensation and were investigated as photocathodes for the hydrogen evolution reaction (HER) under photoelectrochemical conditions. The composite photocathode materials were compared to g-C$_3$N$_4$ powders and were characterized with grazing incidence X-ray diffraction and X-ray photoemission spectroscopy as well as Fourier transform infrared and Raman spectroscopies. Surface modification of polycrystalline CuInS$_2$ semiconducting thin films with photocatalytically active g-C$_3$N$_4$ films revealed structural and chemical properties corresponding to the properties of g-C$_3$N$_4$ powders. The g-C$_3$N$_4$/CuInS$_2$ composite photocathode material generates a cathodic photocurrent at potentials up to +0.36 V vs. RHE in 0.1 M H$_2$SO$_4$ aqueous solution (pH 1), which corresponds to a +0.15 V higher onset potential of cathodic photocurrent than the unmodified CuInS$_2$ semiconducting thin film photocathodes. The cathodic photocurrent for the modified composite photocathode materials was reduced by almost 60% at the hydrogen redox potential. However, the photocurrent generated from the g-C$_3$N$_4$/CuInS$_2$ composite electrode was stable for 22 h. Therefore, the presence of the polymeric g-C$_3$N$_4$ films composed of a network of nanoporous crystallites strongly protects the CuInS$_2$ semiconducting substrate from degradation and photocorrosion under acidic conditions. Conversion of visible light to hydrogen by photoelectrochemical water splitting can thus be successfully achieved by g-C$_3$N$_4$ films synthesized on polycrystalline CuInS$_2$ chalcopyrite electrodes.

Introduction

Photocatalytic and photoelectrochemical (PEC) water splitting using semiconductor materials have attracted considerable attention because of the potential to produce H$_2$ from H$_2$O by utilizing the abundant solar energy.$^1$ One approach to achieve solar-induced water splitting is to employ two photoelectrochemical half-cells, with one cell acting as the photocathode and the other as the photoanode.$^2$

For such systems, the use of relatively small band gap materials ($\text{i.e.}, 1.1$–$1.7$ eV) is desired in order to efficiently absorb light in the range of the terrestrial solar spectrum. Simultaneously, the respective positions of the conduction band minimum and valence band maximum have to be adapted to the standard potentials of H$_2$ and O$_2$ evolution to provide the necessary overall photovoltage ($\sim$1.23 V) required for direct water splitting.

Polycrystalline chalcopyrite thin films have been intensively studied as a material for absorber layers in photovoltaic thin film devices.$^3$ Semiconducting chalcopyrite thin film absorbers such as Cu$_2$Ga$_2$Se$_5$, CuInS$_2$, and Cu(Ga,In)Se$_2$ are very attractive candidates for solar-driven water splitting because they have suitable band gap energies ($\text{ca.} 1.0$–$1.7$ eV),$^4$ and can in principle produce a significant portion of the required photovoltage. Moreover, the fabrication of efficient chalcopyrite thin film absorbers represents a state-of-the-art technology.$^5$ According to recent investigations, chalcopyrites can be successfully employed as photocathodes, i.e. for reduction of protons by light-induced photoelectrons.$^6$ CuInS$_2$ (CIS), for instance, is a p-type semiconductor with a band gap of 1.5 eV providing large photocarrier densities under illumination.$^7$ The highest solar energy conversion efficiency of photovoltaic cells based on CIS materials has been reported to be 11.4%.$^8$ An application for the cathodic half-cell reaction of water splitting, i.e. hydrogen evolution, therefore appears to be possible provided that a stable operation can be achieved upon immersion into an aqueous environment. Upon photoelectrochemical (PEC) water
splitting, photoexcited electrons move towards the CIS-electrolyte interface to induce the reaction \(2\text{H}_2\text{O} + 2\text{e}^- \rightarrow \text{H}_2 + 2\text{OH}^-\). A majority of carriers (holes) move towards the back-contact and through the outer circuit to the counter electrode where oxygen evolves. To perform PEC water splitting, the valence band maximum (VBM) and conduction band minimum (CBM) of the semiconductor electrode have to straddle the standard potentials of hydrogen and oxygen evolution [0 and 1.23 V vs. reversible hydrogen electrode (RHE), respectively]. In acidic solutions, as used in our experiments, protons are already present in the electrolyte, and the CIS interface is employed for the evolution of hydrogen by \(2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\) while water splitting occurs at the Pt-counter electrode.

To date, to the best of our knowledge, no information has been reported in the literature on the capability of g-C3N4/CuInS2 thin film composites as a photocathode material.

Over the past decade, considerable research efforts have been made to investigate polymeric carbon nitride (g-C3N4) due to its specific properties (thermal and chemical stability) predicted by theoretical results. Although this material has a high band gap of \(\sim 2.7\) eV, as determined by UV/Vis diffuse reflectance measurements, many studies have been extensively performed in growing research fields for applications in photochemistry, photocatalysis, and sustainable chemistry, to name a few. Very recently, non-precious metal g-C3N4 has attracted increased interest as a potential material for photocatalytic overall water splitting. Metal-free g-C3N4 was shown to produce both hydrogen and oxygen via water splitting under visible light illumination in the presence of proper sacrificial donor and acceptor materials, respectively. However, most of the studies have been performed on g-C3N4 powders.

In this study we report the application of polycrystalline CuInS2 thin film semiconducting absorber as a photocathode for the production of H2 from acidic aqueous solutions and we will show that the deposition of g-C3N4 films, achieved by direct synthesis on the CuInS2 substrates, has beneficial effects in both stability and charge carrier kinetics. A schematic illustration of the light converting device based on the heterostructure g-C3N4/CuInS2 composite electrode in acidic aqueous solution is shown in Fig. 1. Most of the blue part of the solar spectrum up to 460 nm is captured by the g-C3N4 material due to its high band gap (2.7 eV), while the red portion of the visible light is absorbed by the CuInS2 semiconducting electrode with a smaller band gap (1.5 V). The synthesis of g-C3N4 materials is carried out by thermal polycondensation from dicyandiamide at a temperature of 550 °C. Structural and chemical properties of g-C3N4 materials were investigated using Grazing incidence X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), as well as Fourier transform infrared spectroscopy (FTIR) with ATR mode and Raman spectroscopy. It is shown that synthesized g-C3N4 films on p-type CuInS2 substrates, in terms of structural and chemical properties, are corresponding to the properties of g-C3N4 powders. It is thereby proven that the process of dicyandiamide polycondensation is a suitable method for fabrication of g-C3N4 thin films on semiconductor supports. Moreover, the presence of g-C3N4 thin films on CuInS2 electrodes is found to shift the cathodic photocurrent at potentials up to +0.36 V vs. RHE in 0.1 M H2SO4 aqueous solution (pH 1), which corresponds to a +0.15 V higher onset potential of the cathodic photocurrent compared to the bare CuInS2 electrodes. Furthermore, it will be shown that the formation of g-C3N4 thin films on CuInS2 electrodes results in long-term stable photocurrent densities, monitored during a 22 h period upon hydrogen evolution from H2SO4 containing solutions. The fabrication of g-C3N4 based heterostructures is therefore a promising concept for the conversion of solar energy to chemical energy.

**Experimental section**

**Preparation of the g-C3N4/CuInS2 composite photocathode**

Polycrystalline CuInS2 thin films were prepared by sputtering of metal precursors (Cu and In) followed by sulfurization on soda-lime glass substrates coated with Mo layers, as reported previously. To remove the remaining segregated CuS, formed during the process on the surface, the CuInS2 substrates were etched in 10% KCN solution for 3 minutes. Device-grade chalcopyrite CuInS2 thin films have been prepared by using the well-known RTP technique as described in ref. 5 and 9. Dicyandiamide (C2N4H4) was supplied by Sigma Aldrich. All other chemical reagents used in this study were analytically pure and used without further purification. Polymeric carbon nitride (g-C3N4) films were synthesized onto p-type semiconducting CuInS2 chalcopyrite substrates by thermal polyclondensation of dicyandiamide (C2N4H4) powder at a temperature of 550 °C under an inert nitrogen gas atmosphere. Dicyandiamide powder was deposited on the CuInS2 chalcopyrite substrates and heated from 25 °C to 550 °C at a rate of 50 °C min⁻¹. After reaching the maximum temperature, the samples were kept at 550 °C for 10 min by which the preparation of the g-C3N4/CuInS2 thin film composite electrodes was completed. Subsequent analyses were carried out immediately after sample preparation.
Characterization

Fourier transform infrared (FTIR) spectroscopy with ATR mode and Raman spectroscopy were carried out with FTIR Bruker Equinox 55 and Raman Bruker FRA 106/S spectrometers, respectively, to investigate the vibrational properties of the material. FTIR and Raman spectra were measured with a resolution of 2 and 4 cm\(^{-1}\), respectively.

X-Ray Diffraction (XRD) patterns were measured with a Bruker AXS (D8 Advance) diffractometer by using Cu K\(_\alpha\) radiation (\(\lambda = 1.5418\) Å) to characterize the crystallographic structure of the g-C\(_3\)N\(_4\) material.

X-ray photoelectron spectroscopy (XPS) was performed with a Phoibos spectrometer using a monochromatized Mg K\(_\alpha\) (hv = 1253.6 eV) X-ray radiation source to investigate the chemical and electronic states at the surface. The core level spectra have been deconvoluted by a fitting procedure using Voigt line shapes (combination of Gaussian–Lorentzian functions) after Shirley background subtraction. XPS spectra of the g-C\(_3\)N\(_4\) powder have been multiplied by a factor of five for better clarity.

For UPS measurements, a helium lamp providing the He I line at hv = 21.21 eV was used. The secondary electron cutoff region was recorded with a sample bias at \(-5\) V. An uncertainty error of \(\pm 0.1\) eV is estimated relative to the spectrum.

Scanning electron microscopy (SEM) was carried out with a LEO GEMINI 1530 scanning electron microscope, with an acceleration voltage of 10 kV.

Results and discussion

In Fig. 3, XRD analysis of the g-C\(_3\)N\(_4\) powder as well as the g-C\(_3\)N\(_4\) film synthesized on CuInS\(_2\) electrodes is shown. Two prominent features are visible: (i) the small peak at 13.1° corresponds to a lattice distance of \(d = 0.676\) nm which is related to the in-plane structural packing of nitrogen-linked heptazine units and (ii) the prominent peak at 27.5° is characteristic of an interplanar stacking distance of aromatic units, as known for the graphite lattice. The stacking distance of the aromatic units is calculated to be \(d = 0.324\) nm. These two peak positions are in good agreement with previously published reports.\(^{11,13}\) Comparison of XRD data for the powder and the film proves that the polycondensation process of dicyandiamide results in identical structural properties. Moreover, a comparative investigation with UV/Vis diffuse reflectance and photoluminescence spectra indicates similar optical properties for both the powder and the film (not shown here). For both
materials the onset of the absorption has been deduced to be 2.7 eV. These results demonstrate the successful preparation of g-C3N4 films on semiconducting CuInS2 electrodes.

Fig. 4a displays the XPS survey scans of the g-C3N4 powder and a g-C3N4 film on the CuInS2 electrode. Core level analysis of C 1s and N 1s, respectively, are shown in Fig. 4b and 4c. The survey scans indicate the presence of carbon, nitrogen, and oxygen in the g-C3N4 powder as well as in the g-C3N4 film. As reported earlier, oxygen contributions result from the exposure to ambient atmosphere and can be removed from the surface by an appropriate annealing process.17 The inset in Fig. 4a shows the onset of secondary electrons upon excitation with He I. The determination of the work function (ϕ) for the g-C3N4 film on CuInS2 substrates is deduced graphically from the linear extrapolation of the secondary electron cutoff edge to the background emission intensity. The g-C3N4 modified CuInS2 electrode shows a work function of ϕ = 4.3 (1) eV with a remaining small surface oxide layer after the PEC performance testing. Post-thermal treatment up to 300 °C removes this surface oxide and the work function decreases to 4.0 (1) eV (not shown here; see ref. 17). Unmodified polycrystalline CuInS2 is characterized by a work function of $\phi = 5.5$ (1) eV. The difference in the respective values for $\phi$ between the g-C3N4 film on CuInS2 and the unmodified CuInS2 substrate induces a space charge region and, hence, an electric field at the interface leading to charge carrier separation under illumination.

High-resolution XPS of the C 1s core level spectra of the g-C3N4 film synthesized on CuInS2 chalcopyrite substrates reveals three main components. The peak at lower binding energy (BE), centered at 285.1 eV, can be attributed to carbon contamination, i.e. C–C, C–H, and/or C=C bonds. The two other components at higher BE at 287.2 and 290.4 eV, respectively, are also observable on the C 1s core level spectrum of the g-C3N4 powder. The g-C3N4 powder only reveals these two peaks, indicating no contamination of aliphatic carbons. The main prominent peak at 290.4 eV is attributed to sp$^2$ carbon–nitrogen bonds of the aromatic ring system – i.e. the s-triazine unit – pyridine-like structure.17 The peak at lower BE at 287.2 eV is assigned to tertiary nitrogen N–(C)3 groups, i.e. nitrogen trigonally bonded to three sp$^2$ carbon atoms in the C–N network (graphitic-like nitrogen structure).

The N 1s core level spectra show a broad peak centered at 401.2 eV with a shoulder at higher BE. Deconvolution of the data for the g-C3N4 powder reveals contributions of three peaks at 401.1, 403 and 406 eV, respectively. The small peak at 406 eV can be attributed to residual nitrite-like (NO2) groups at the surface/near-surface region. In the case of the g-C3N4 film on CuInS2 chalcopyrite substrates, a further contribution at lower BE at 397.8 eV can be observed. The dominant nitrogen peak at 401.1 eV is attributed to nitrogen atoms in an sp$^2$-configuration and bonded to two carbon atoms (s-triazine rings, pyridine-like nitrogen atoms). The other peak at higher BE at 403 eV is ascribed to tertiary nitrogen N–(C)3 groups, i.e. nitrogen trigonally bonded to three sp$^2$ carbon atoms in the C–N network (bridge, graphitic-like nitrogen structure). Here again, the N 1s core levels of the g-C3N4 film on CuInS2 substrates are in good agreement with those of the g-C3N4 powder. The region at 401–403 eV is generally referred to as quaternary nitrogen, i.e. as “graphitic” nitrogen when the nitrogen atom is incorporated into the graphene layer, replacing therein a carbon atom.18

![Fig. 4 XPS spectra of the g-C3N4 powder (data shown in red) and a g-C3N4 film on the CuInS2 electrode (data shown in black): (a) survey spectra, (b) C 1s core level spectra, and (c) N 1s core level spectra. The C 1s and N 1s spectra were fitted with a Voigt function (convolution of Gaussian-Lorentzian sum functions) after Shirley background subtraction. The inset in (a) shows the secondary electron cutoff edge of the g-C3N4 film on CuInS2.](image)

![Fig. 5 (a) FTIR spectra and (b) Raman spectra of the g-C3N4 powder (red curve) and a g-C3N4 film on CuInS2 (black curve).](image)
Fig. 5 depicts the (a) FTIR and (b) Raman spectra of the g-C₃N₄ powder and a g-C₃N₄ film on CuInS₂, respectively. As expected, FTIR and Raman spectra of both the g-C₃N₄ powder and the g-C₃N₄ film on CuInS₂ are quite similar, indicating that the g-C₃N₄ film prepared on the CuInS₂ chalcopyrite electrode presents identical vibrational modes as the g-C₃N₄ powder. FTIR and Raman spectra are in good agreement with previously reported data.¹⁹–²¹

In the FTIR spectrum of the g-C₃N₄ powder, the broad set of intense peaks between 900 and 1700 cm⁻¹ is characteristic of s-triazine derivatives’ vibrational modes like C–N and C≡N stretching modes,²⁶ indicating that nitrogen is chemically bonded to carbon in the g-C₃N₄ material. The peak at 805 cm⁻¹ is assigned to the breathing vibrational modes of s-triazine units.²¹,²⁴,²⁵ At higher wavenumbers, another broad set of low intensity peaks between 3000 and 3300 cm⁻¹ can be observed and is attributed to the presence of the stretching vibrational modes of primary (≡NH₂) and secondary (=N–H) amines suggesting the hydrogenation of some nitrogen atoms in the g-C₃N₄ material.¹⁹,²⁷,²⁸ These peaks are also associated with amine bridges. Moreover, a small absorption peak at 2157 cm⁻¹ can be noticed, and is assigned to the cyano terminal group (≡N) and cumulated double bond (–N≡C–N= and similar species) in the powder.²⁷

Raman spectra of both the g-C₃N₄ powder and the g-C₃N₄ film are quite similar, and show two major broad set of peaks. The two peaks at ~1370 and ~1570 cm⁻¹ are attributed to the D (for disorder) and G (for graphite) peaks, respectively, which are related to sp² carbon materials.²⁵,²⁸ At higher wavenumbers, two further broad peaks of low intensity can be observed and are characteristic of the second-order Raman features of D and G peaks, respectively, which arise from overtones of modes with “in-plane” atomic displacements.²⁵,²⁹ A further set of peaks is observable at lower wavenumbers, indicating the lattice vibrational and the internal modes, respectively.

In Fig. 6, the surface morphology of (a) the CuInS₂ chalcopyrite electrode and (b) the g-C₃N₄ film deposited on CuInS₂ is investigated by SEM. The top view SEM micrograph in Fig. 6a indicates that the CuInS₂ film has a dense and rough surface, which consists of compact agglomerates of angular-shaped crystallites. From the cross-sectional SEM micrograph of the corresponding CuInS₂ electrode a film thickness of 2–3 μm can be deduced.

The surface morphology of the g-C₃N₄ film is observed to be highly porous consisting of craters and ditches on the μm scale (see Fig. 6b, upper SEM image). The thickness of the g-C₃N₄ film is typically in the range of 80–100 μm, as can be observed on the cross-sectional micrograph (Fig. 6b, lower SEM image). As shown in the inset of the cross-sectional micrograph in Fig. 6b, the deposition of the g-C₃N₄ film does not result in a homogeneous coverage of the CuInS₂ surface. However, due to its high porosity, which realizes a large surface area, the modified CuInS₂ electrode is promising as a photocathode material since a large surface area can considerably improve the photo-electrochemical performance. Additionally, photographs of the measured CuInS₂ chalcopyrite and the g-C₃N₄/CuInS₂ composite electrodes are inserted on the upper micrograph of the respective SEM images. One can observe with the naked eye the color changes of the electrode surface from dark-grey to yellow, which indicates good coverage of the CuInS₂ electrode by g-C₃N₄ films.

Current density–potential curves of the bare CuInS₂ electrode and g-C₃N₄ on the CuInS₂ electrode immersed in 0.1 M H₂SO₄ aqueous solution under intermittent light irradiation of 1 sun, are shown in Fig. 7. Additionally, the typical cathodic polarization curves of both CuInS₂ and g-C₃N₄ modified CuInS₂ electrodes in the dark (solid line) and under light irradiation of 1 sun (dash-dotted line), respectively, are also presented in Fig. 7. The potential was swept at a scan rate of 5 mV s⁻¹ towards more positive potentials. The unmodified CuInS₂ electrode reveals a current density of about 50 μA cm⁻² at an
applied potential of $-0.6 \text{ V}_{\text{Ag/AgCl}}$ in the dark. Under illumination of 1 sun, a cathodic photocurrent density of about $-0.3 \text{ mA cm}^{-2}$ is reached, corresponding to a net photocurrent density of $\sim 250 \mu \text{A cm}^{-2}$. This result emphasizes the applicability of CuInS$_2$ as a hydrogen evolving photocathode.

Many electrochemical studies on chalcopyrites (CuFeS$_2$, CuInS$_2$, CuGaSe$_2$, Cu(In,Ga)Se$_2$, for instance) have already been performed in a variety of aqueous electrolytes covering the whole pH range in order to understand the electrochemical processes which occur at the semiconductor–liquid interface.\textsuperscript{30–40} Several irreversible reactions can occur at the surface resulting in degradation of the material. It is known that by polarizing the electrode with anodic potential under light, competitive reactions can occur, resulting in dissolution of the metals as cations, aggregation of elemental sulfur at the surface or formation of soluble oxygenated species. Those reactions can cause significant (photo)corrosion and considerably limit the conversion of solar energy into chemical energy. Moreover, some oxidative photodecomposition reactions of CuInS$_2$ in aqueous acidic solutions are listed in the report of Cattarin et al.\textsuperscript{35} Thus, at the rest potential or higher anodic potential range applied in this study, several reactions can occur leading to the formation and/or the presence of several chemical species such as covellite (CuS), chalcocite (Cu$_2$S), cations (Cu$^+$, Cu$^{2+}$, and/or In$^{3+}$) or elemental sulfur (S) to name the principal ones.\textsuperscript{33,34} However, the dissolution of metals from the chalcopyrite is slow, even in highly acidic solutions, and successful methods are well-known in leaching copper.\textsuperscript{41,42} In order to test if any dissolution or photocorrosion process at the semiconductor/liquid interface may interfere with the reduction of protons, cyclic voltammetry studies were performed in the dark and under illumination. The absence of reduction and oxidation peaks in the cathodic and anodic regions, respectively, suggests that soluble species like covellite and/or chalcocite (which are involved in the reduction and oxidation processes) are not present or do not exceed negligible amounts in our system. Charge transfer appears therefore not to be dominated by (photo)corrosion even in this aggressive electrolyte. It is therefore assumed that the measured photocurrent density predominantly results from light-induced hydrogen evolution.\textsuperscript{37,38} These observations support the conclusion that polycrystalline CuInS$_2$ thin films can act as a photocathode in a PEC device for water splitting. Thus, the H$^+$ protons are photoelectrochemically reduced to hydrogen gas under acidic conditions at cathodic potentials. Moreover, polycrystalline CuInS$_2$ was found to generate cathodic photocurrents at potentials up to $+0.21 \text{ V vs. RHE}$ in 0.1 M H$_2$SO$_4$ aqueous solution. This onset potential and the measured photocurrent are higher than those of the Pt/CuInGaSe$_2$ substrate in the same electrolyte as reported by Domen et al.\textsuperscript{8} This result demonstrates that the CuInS$_2$ photoelectrode reveals a more positive onset potential by about $+0.11 \text{ V}$ than the Pt/CuInGaSe$_2$ heterojunction. It is known that the photocurrent onset is related to the kinetics of the electron transfer at the solid–liquid interface. Therefore, our observations provide clear evidence for the improved rate of electron transfer at the interface of the CuInS$_2$ electrode.

With introduction of the g-C$_3$N$_4$ surface film, this onset potential is furthermore shifted to a higher anodic potential by about $+0.15 \text{ V}$ in comparison to the bare semiconducting CuInS$_2$ electrodes as shown in Fig. 7. Therefore, cathodic photocurrents are generated at potentials up to $+0.36 \text{ V}$ relative to the hydrogen redox potential which points to beneficial band alignment between the film and the substrate, i.e. a negative (downward) band bending in the chalcopyrite, corresponding to the difference of the respective work functions. In a recent report, the photoactivity of g-C$_3$N$_4$/CuGaSe$_2$ composites has been investigated.\textsuperscript{37} In comparison to this heterojunction, the g-C$_3$N$_4$ film on the CuInS$_2$ electrode shows a strong enhancement by a factor 50.\textsuperscript{47} However, in comparison to the bare CuInS$_2$ substrate, the photocurrent response of the heterosystem appears to be reduced by almost 60%. This observation suggests considerable light absorption losses in the g-C$_3$N$_4$ film. Those losses have to be ascribed to the low charge carrier lifetimes in the g-C$_3$N$_4$ film which are discussed further below in more detail. Transfer of electrons, photogenerated in the substrate, is therefore presumably restricted to sites where the g-C$_3$N$_4$ film is ultrathin, reducing thus the effective electrode area and the overall photocurrent density. The films, as investigated here, therefore act as protective surface coverage of the CuInS$_2$ substrate and allow for shifting of the onset potential for hydrogen evolution to more positive values. They limit, however, the conversion efficiency of incident photons to charge carriers.

It is expected that further improvements in film fabrication will help overcome this detrimental side-effect. Dwell time and heating temperature rate, for instance, both play an important
role in smoothness of the film, adhesion to the substrate and electronic properties. Moreover, deeper insight into the photoactivity of the resulting g-C$_3$N$_4$ films is required and will be gained by wavelength-dependent photoelectrochemical measurements with and without photoresponsive substrates. These studies are underway and will be discussed in a future report.\(^{43}\)

To examine the stability of the cathodic photocurrent generated by the g-C$_3$N$_4$/CuInS$_2$ composite electrodes, a constant potential of $-0.5$ V vs. Ag/AgCl was applied. The time course of the photocurrent for g-C$_3$N$_4$/CuInS$_2$ composite electrodes immersed in 0.1 M H$_2$SO$_4$ aqueous solution under continuous visible light irradiation of 1 sun is shown in Fig. 8. The inset in Fig. 8 depicts the magnification of the change in the photocurrent between 0 and 240 min. The composite electrode was first measured in the dark during the first 5 min and then the electrode was illuminated continuously by visible light ($\lambda > 400$ nm) for 22 h. The cathodic photocurrent increased constantly for about 3 h to reach about 50 $\mu$A cm$^{-2}$ and then kept constant at an almost steady value for more than 19 h. After 22 h the light was turned off to confirm that the observed current was light-induced. The increase of the photocurrent during the first 3 h is probably arising from the time needed for the acidic solution to remove remnant segregated materials from the surface, which presents defect surface states and acts as surface recombination centers of photo-generated electron–hole pairs, as also reported for another system (InGaN electrode).\(^{44}\) After this first period of time, the heterostructure system (g-C$_3$N$_4$/CuInS$_2$) maintains a constant photocurrent value for about 19 h. As pointed out above, no indications were found for cathodic decomposition of the heterostructure. This result indicates, therefore, that our heterostructure system is highly resistant to reductive decomposition, and presents high photocorrosion and degradation resistance under acidic conditions. Moreover, analysis of the evolved gaseous products by an in-line system mass spectrometer confirmed the evolution of H$_2$ and O$_2$.\(^{45}\) The results of Fig. 8 are therefore interpreted as proof for the long-term stability of the photocathode. This stability is first and foremost attributed to the presence of the polymeric g-C$_3$N$_4$ network that allows – to a limited extent – transfer of photogenerated electrons from the substrate to the electrolyte while direct contact of the chalcopyrite to the acidic solution is suppressed.

Finally, the electronic and optical properties of the investigated heterostructure are discussed in more detail. Chalcopyrites are known to show high solar-to-electric conversion efficiencies, which are attributed to strong optical absorption (due to the direct bandgap) and their exceptional carrier transport properties. Herein, CuInS$_2$ electrodes with a bandgap energy of 1.5 V closely match the visible part of the solar spectrum. Polymeric g-C$_3$N$_4$ with its bandgap of approximately 2.7 eV can solely absorb effectively a moderate fraction of the solar spectrum. In practice, the operating point of an effective PEC semiconductor film (here, the heterostructure composite device) depends on the energetics (band edge positions) and electrode kinetics (overpotentials). In the photocathode configuration, a proper band edge alignment is critical to minimize the required additional voltage bias from underlying junctions to achieve high-efficiency PEC water splitting.

In Fig. 9, an idealized energy band diagram of the heterostructure g-C$_3$N$_4$/CuInS$_2$ composite is proposed. The band edge alignment of the composite photocathode is based on the XPS/UPS analysis (see Fig. 4). The electrochemical and the absolute scale of both the hydrogen reduction potential, $\mu_{e^-}/H_2$, and the water oxidation potential, $\mu_{e^+/H_2O}$, are also presented on the right side. From the literature, $\mu_{e^-}/H_2$ is referred to the vacuum level, $E_{\text{vac}}$, with values in the range between 4.4 and 4.7 eV.\(^{46-49}\) Here, $\mu_{e^-}/H_2$ was chosen to be equal to 4.6 eV corresponding to

![Fig. 8](image) Time course of the photocurrent for the g-C$_3$N$_4$/CuInS$_2$ electrode in 0.1 M H$_2$SO$_4$ aqueous solution (pH 1) under continuous irradiation of visible light ($\lambda > 400$ nm). The potential was kept at $-0.5$ V vs. Ag/AgCl reference electrode. The inset shows the magnification of the change in photocurrent for the g-C$_3$N$_4$/CuInS$_2$ electrode between 0 and 240 min.

![Fig. 9](image) Proposed energy band diagram of the g-C$_3$N$_4$–CuInS$_2$ heterosystem. The respective work functions, $\Phi$, electron affinities, $\chi$, and the resulting band-edge alignments are shown as deduced from the XPS/UPS analysis. The electrochemical and the absolute scale are given on the right side. The hydrogen redox potential is indicated as $\mu_{e^-}/H_2$, and the water redox potential as $\mu_{e^+/H_2O}$.

\(^{43}\) The derived energetic position of the CBM of $\sim 3$ eV – i.e. the electron affinity, $\chi$ – is negative versus $\mu_{e^-}/H_2$, which allows the heterostructure composite electrode to operate as the hydrogen evolving photocathode with reduced overpotentials. $E_{\text{onset}}$ denotes the quasi-Fermi level for excess minority electrons and $V_{OC}$ represents the open circuit voltage under illumination.
the redox potential of the normal hydrogen electrode, NHE. For the heterostructure based g-C3N4 films, the electron affinity has to be smaller than \( \mu_{e}^{H+/H^0} \) in order to efficiently transfer electrons to protons in solution. Our very recent photoemission results of g-C3N4 films, covered with a thin surface oxide, suggest a work function of \( \Phi = 4.3 \pm 0.1 \) eV after photoelectrochemical operation and an energetic distance between the valence band maximum, \( E_{\text{VBM}} \), and the Fermi level, \( E_F \), of \( \Delta_{\text{VBM}} - E_F = 1.4 \pm 0.3 \) eV. Considering the band gap energy of g-C3N4 films, \( E_g = 2.7 \pm 0.1 \) eV, the electron affinity of g-C3N4 films is deduced to be about 3 eV relative to \( E_{\text{vac}} \). These results are indicative of an intrinsic g-C3N4 semiconductor and a conduction band maximum, \( E_{\text{CBM}} \), of g-C3N4 energetically positioned above the hydrogen redox potential \( \mu_{e}^{H+/H^0} \).

According to the different work functions, \( \Phi_{\text{g-C3N4}} \) and \( \Phi_{\text{CuInS2}} \), of the surface film and substrate, Fermi-level equilibration takes place upon contact of the two materials, g-C3N4 and CuInS2. Due to the much higher conductivity of the substrate, a space charge region is mainly created in the chalcopyrite as shown in Fig. 9. The strength of the resulting band bending can be approximately deduced from the difference \( \Delta \Phi = \Phi_{\text{g-C3N4}} - \Phi_{\text{CuInS2}} \). Under illumination, separation of photo-generated carriers occurs at the interface of the heterostructure, accelerating thereby electrons towards the solid–liquid interface and holes towards the front-contact. With its protective function, the g-C3N4 film additionally suppresses defects formation at the CuInS2 interface. At sites where the g-C3N4 film is thin enough, interface recombination is reduced and electron transfer towards the electrolyte is enhanced. Therefore, g-C3N4 films seem to act mostly as passivation layers in the study presented here and improve the stability of the composite electrode (see Fig. 8) by reducing the surface and interface states, which play an important role in photocurrent losses due to recombination processes.

In the case of the bare CuInS2 electrode with a bandgap energy of 1.5 V, light with wavelength energy below 830 nm is absorbed. In contrast, only a moderate fraction of the solar spectrum can be effectively absorbed by the g-C3N4 film due to its bandgap of approximately 2.7 eV. Moreover, it is known that a bandgap between 2.5 and 2.8 eV of the most common films used for PEC could limit achievable photocurrents. Therefore, it is clear that the CuInS2 electrode beneath the g-C3N4 film can only absorb photons within the wavelength range of 460–830 nm (i.e., \( 1.5 \text{ eV} < h\nu < 2.7 \text{ eV} \)), i.e. below the bandgap of the polymeric carbon nitride. Due to the short charge carrier lifetimes in the g-C3N4 film, photoelectrons excited by light with wavelengths >460 nm can only contribute to the photocurrent response where the film thickness is in the nm range. Otherwise, recombination takes place and attenuates the measured photocurrent density.\(^{35,52}\) Transient photoluminescence studies on g-C3N4 revealed recently an estimated value of the charge carrier lifetimes of the order of 3 ns due to charge localization and native defects.\(^{52}\) Therefore, the polymeric carbon nitride structure is characterized by short minority carrier diffusion lengths (<2 nm) that prevent efficient charge transfer in thick films. The thickness of the g-C3N4 film is therefore the key issue in designing an efficient heterostructured photocathode. For this reason, controlling the film thickness will be of major importance for future device development. It is envisaged that those ultrathin films can simultaneously fulfill the requirements as a protective layer and as an electronically active layer without limiting the transfer of photoinduced electrons towards the electrolyte.

**Conclusions**

For the first time, we have provided clear evidence for the beneficial role of polymeric carbon nitride films, g-C3N4, as a protective layer on CuInS2 photocathodes. The photoelectrochemical performance of the g-C3N4 film/CuInS2 heterostructure under an illumination of 1 sun was observed to stably operate for 22 h in acidic electrolytes. The conversion of solar energy to chemical energy could be confirmed by mass spectrometric detection of evolving \( \text{H}_2 \) and \( \text{O}_2 \). Extensive analysis of photoelectron spectroscopy results was used to devise a band diagram of the junction with respect to the absolute as well as electrochemical scale. From this analysis it follows that the g-C3N4 film assumes also an important electronic role upon contact formation with the CuInS2 substrate. Fermi-level equilibration leads to a downward band bending in the substrate and, correspondingly, to a more positive onset potential for hydrogen evolution than observed for the bare substrate. On the other hand, the rate of electron transfer towards the electrolyte is limited by short charge carrier lifetime in thicker regions of the g-C3N4 film. Future developments will therefore focus on the design of ultrathin coverage with a g-C3N4 film in order to improve the overall photocurrent output as well.

**Acknowledgements**

The authors would like to thank C. Ferber for the KCN etching of the CuInS2 electrodes and J. Albert for providing the SEM images. Financial support granted by the BMBF excellence cluster project “Light2Hydrogen” (grant no. 03IS2071F) is gratefully acknowledged.
