It is demonstrated numerically that by using Pyragas' method of chaos self-control a stable semiconductor oscillator can be designed based on driven real-space transfer oscillations in a modulation-doped heterostructure. By application of a small time-continuous delayed feedback voltage control signal, different unstable periodic orbits embedded in the chaotic attractor can be stabilized. Thus different modes of self-generated periodic voltage oscillations can be selected by choosing an appropriate delay time. This provides tunability to different discrete frequencies.

1. Introduction

Recent theoretical and experimental efforts to control chaotic behaviour in physical systems, that is, to convert chaotic behaviour to a periodic time dependence, have shed a new light on the role of chaotic dynamics in view of practical applications. It turns out that the presence of chaos, when controllable, can be advantageous. We demonstrate this for the case of electrical instabilities in the regime of nonlinear hot carrier transport [1–3], which can be used in semiconductor devices as microwave oscillators [4]. By applying a small self-control, we achieve stable and tunable regular oscillations. Our underlying principle is based upon the observation that any chaotic attractor of a nonlinear dynamic system contains an infinite dense set of unstable periodic orbits (UPO). As shown by Ott, Grebogi and Yorke (OGY) [5], any of these UPOs may be stabilized by applying a small time-dependent perturbation to the control parameter of the system such that the trajectories are thrown onto the stable manifold of the particular UPO. Thus the inherent chaotic dynamics create a flexible situation in which it is possible to choose between quite different periodic orbits using only a small control.

A disadvantage of the OGY method is that the feedback control is applied only at discrete points of time given by the return times of the Poincaré map of the dynamic flow, which has to be computed for this purpose. The method can thus stabilize only those UPOs whose largest Lyapunov exponent is small compared to the reciprocal time interval between the parameter changes. A novel, powerful method of chaos control by a small time-continuous perturbation which does not require on-line computations has been proposed by Pyragas [6]. The stabilization of UPOs is achieved by adding a delayed self-controlled feedback to one of the dynamic equations. Here we numerically demonstrate that a simple and stable tunable semiconductor oscillator can be built on this principle.

2. Model

We consider nonlinear charge transport parallel to the layers of the modulation-doped GaAs/Al$_x$Ga$_{1-x}$As heterostructure schematically shown in Figure 1(a). In experiments the system displays N-shaped negative differential conductivity (NNDC) [7], ac-driven current oscillations [8] and spontaneous oscillations under dc bias [9–12]. The heterostructure consists of a GaAs layer of width $L_1$ and an Al$_x$Ga$_{1-x}$As layer of width $L_2$. At the layer interface the conduction band displays a discontinuity $\Delta E_C$ as shown in Figure 1(b). The Al$_x$Ga$_{1-x}$As layer is heavily n-doped with donor density $N_D$. In thermodynamical equilibrium the donors are ionized, and the valence electrons, separated from their parent donors in the Al$_x$Ga$_{1-x}$As layer, fall into the lower potential of the GaAs well. There they experience strongly reduced impurity scat-
The modulation doped GaAs/Al$_x$Ga$_{1-x}$As heterostructure in an external circuit with load resistance $R_L$ and bias voltage $U_0$. $L_1$ and $L_2$ are the heterolayer widths.

Energy-band diagram versus the vertical coordinate $x$. The conduction band has a discontinuity $\Delta E_C$ at the interface, and band bending in the Al$_x$Ga$_{1-x}$As layer results in the interface potential barrier $\Phi_B$. Application of an electric field parallel to the layer interface induces carrier heating, and for a field $\varepsilon_\parallel > 2$ kV/cm thermionic emission of electrons across the barrier into the Al$_x$Ga$_{1-x}$As is possible. This leads to an increased carrier density $n_2$ in the Al$_x$Ga$_{1-x}$As, where the electron mobility $\mu_2$ is much lower due to strongly enhanced impurity scattering, and a reduced density $n_1$. Thus for the longitudinal current, increasing the voltage results in a reduced average mobility, and there exists a regime of negative differential conductivity. The current-voltage characteristic has the shape of an $N$, which is in analogy to the Gunn effect, where the underlying physical mechanism is the transfer of electrons from a state in momentum space with high mobility to a state of low mobility (intervalley transfer in $k$-space).

A physical mechanism for self-generated current oscillations under dc bias conditions has been proposed [13], based upon the coupled nonlinear dynamics of real-space electron transfer and of the space-charge in the doped Al$_x$Ga$_{1-x}$As layer, which controls the potential barrier $\Phi_B$. The dynamics can be described by a set of nonlinear differential equations for the spatially averaged carrier density $n_1$ in the GaAs layer, the parallel electric field $\varepsilon_\parallel$ and the potential barrier $\Phi_B$ [14].

The alteration in time of $n_1$ is expressed in the continuity equation

$$\dot{n}_1 = \frac{1}{e L_1} (J_{1\to 2} - J_{2\to 1})$$

with the transversal thermionic-emission current densities given by Bethe’s theory:

$$J_{1\to 2} = -e n_1 \sqrt{\frac{E_1}{3 \pi m_1^*}} \exp\left(-\frac{3 \Delta E_C}{2 E_1}\right),$$

$$J_{2\to 1} = -e n_2 \sqrt{\frac{E_2}{3 \pi m_2^*}} \exp\left(-\frac{3 \Phi_B}{2 E_2}\right),$$

where $m^*$ are the effective masses and $E_i = \frac{3}{2} k_B T_i$ are the mean carrier energies given by the carrier temperatures $T_i$. The mean energy as a function of the applied electric field is estimated at $E_i \approx E_i + \tau_{E_i} \tau_{E_i}^* e \mu_i \varepsilon_\parallel^2$, with the thermal equilibrium mean energy $E_i = \frac{3}{2} k_B T_i$, where $T_i$ is the lattice temperature, and energy relaxation times $\tau_{E_i}$. Because of local charge neutrality, the carrier density $n_2$ in the Al$_x$Ga$_{1-x}$As layer can be eliminated as a dependant variable: $n_2 = N_D - n_1 L_1/L_2$.

The dielectric relaxation of the parallel electric field is described by the equation

$$\varepsilon \dot{\varepsilon}_\parallel = -\sigma_L (\varepsilon_\parallel - \varepsilon_0) - \frac{e n_1 \mu_1 L_1 + e n_2 \mu_2 L_2}{L_1 + L_2}$$

with $\sigma_L = d/[h(L_1 + L_2)R_L]$ and $\varepsilon_0 = U/d$. Here $\varepsilon$ is the permittivity and $R_L$ is the load resistance (see Figure 1).

The space charge in the Al$_x$Ga$_{1-x}$As layer results in an internal electric field $\varepsilon_\perp$ perpendicular to the layer, which is described by Poisson’s equation $\varepsilon \varepsilon_\perp \partial^2 \varepsilon_\perp/\partial x^2 = e (N_D - n(x))$ and the balance equation for the transverse current $e \dot{\varepsilon}_\perp (x, t) + e \mu_2 n (x, t) \varepsilon_\perp (x, t) = 0$.

For the dynamics of the potential barrier \( \Phi_B = -e \int_0^L \rho_i(x, t) \, dx \) we obtain the equation
\[
\Phi_B = e \left( -\mu_2 N_D \Phi_B + \mu_2 \frac{e^2}{2\epsilon} L_1^2 n_1^2 \right). \tag{3}
\]
Together, (1)–(3) describe the dynamics of real space transfer in the heterostructure.

3. Numerical Results

We have numerically simulated the dynamics of the system using the parameters in Table 1. Apart from self-generated periodic oscillations [14], the semiconductor can display chaotic oscillations if it is periodically driven by a bias voltage \( U(t) = U_0 + U_{ac} \cdot \sin(2\pi f_d t) \). Figure 2 shows a phase portrait and a Poincaré section for the driven system. The strange attractor has the shape of a torus with a thickened, folded surface. In the Poincaré section four “wings” are visible, each in a different stage of the nonlinear folding mechanism. This kind of structure is typical for nonlinear oscillators with a periodic driving force [17] and is sometimes referred to as a Birkhoff-Shaw attractor.

We will now apply time-continuous chaos control to the driven system. This involves coupling the perpendicular voltage drop within the \( \text{Al}_{x}\text{Ga}_{1-x}\text{As} \) barrier \( \Phi_B/e \) back to the dynamics of \( \Phi_B \), and may be realized by introducing a gate electrode on top of the GaAs layer to which the feedback signal \( \delta \Phi_B \) is applied. The perturbation \( \delta \Phi_B \) takes the specific form of the difference between the system output \( \Phi_B(t) \) and the delayed output \( \Phi_B(t - \tau) \) (delayed feedback control). The dynamics of the potential barrier is then given by
\[
\Phi_B = e \left( -\mu_2 N_D \Phi_B + \mu_2 \frac{e^2}{2\epsilon} L_1^2 n_1^2 \right) + K \delta \Phi_B, \tag{4}
\]
\[
\delta \Phi_B(t) = [\Phi_B(t - \tau) - \Phi_B(t)]. \tag{5}
\]
Here \( \tau \) is a suitably chosen delay time and \( K \) is an experimentally adjustable perturbation weight. If \( \Phi_B(t) \) is periodic with period \( \tau \), the difference term vanishes, and the system dynamics have the unperturbed form (\( \delta \Phi_B = 0 \)). Therefore a UPO of the unperturbed system with period \( \tau \) remains a solution if the control is switched on. The stabilization of this UPO can be achieved by an appropriate choice of \( K \). This method has the advantage that the UPO need not to
be known explicitly. Experimentally, only a simple delay line is necessary. The disadvantage is that two control parameters, $\tau$ and $K$, have to be adjusted within a relatively small range to be determined empirically. The amplitude of the feedback signals $\delta \Phi_B(t)$ can be considered as a criterion for UPO stabilization. When the system moves along its UPO this amplitude is extremely small. We shall assume $\langle D^2(t) \rangle \ll 1$ as a criterion for stabilization, defining the dimensionless control signal $D(t)$ as follows:

$$D(t) = \frac{\delta \Phi_B(t)}{\Phi_B^*} = \frac{[\Phi_B(t + \tau) - \Phi_B(t)]}{\Phi_B^*},$$

where $\Phi_B^* \equiv 11.7$ meV has been chosen as reference value, and $\langle \rangle$ denotes the temporal average.

Figure 3 shows the stabilization of a period-five limit cycle. After the control signal is switched on at $t_c = 80$ ps, the amplitude $D(t)$ of the perturbation rapidly decays after a transient process and the system moves into the periodic regime corresponding to an initially unstable orbit of the unperturbed system. The delay time of the controlling feedback signal is equal to the period of the limit cycle, which gives an oscillation frequency of $f = 58.6$ GHz. This corresponds to $1/5$ of the driving frequency $f_d$. Fig. 3(c) depicts the phase portrait for the post-transient regime. Comparison with Fig. 2(a) shows that the stabilized limit cycle is indeed embedded in the chaotic attractor of the unperturbed system.

By choosing a different delay time for the feedback signal, a different UPO can be stabilized for the same driving frequency and amplitude. Figure 4 shows the stabilization of a period-three UPO of the chaotic attractor, with an oscillation frequency of $f = 97.7$ GHz, corresponding to $1/3$ of the driving frequency $f_d$. Here the control signal $D(t)$ does not run to zero but oscillates with a small amplitude. This effect is not expected in theory, and it is not yet well understood although it has been observed in numerical simulations of other systems [6, 18]. The fact that the effect is rather pronounced in this case may be due to the nature of the unperturbed system, which is periodically driven in time. However, the criterion for stabilization given above is satisfied.

Although the amplitude of perturbation becomes very small after a transient period, depending on initial conditions it can reach rather high values immediately after control is switched on. From the experimental point of view, it is undesirable that the accessible system parameter to which control is applied should experience strong bursts as shown in the simulations. Therefore we introduce a restriction to the delayed feedback signal as follows:

$$D(t) = \begin{cases} -D_0, & \text{when } K \delta \Phi_B(t) \leq -D_0, \\ K \delta \Phi_B(t), & \text{when } -D_0 < K \delta \Phi_B(t) < D_0, \\ D_0, & \text{when } K \delta \Phi_B(t) \geq D_0. \end{cases}$$

Fig. 3. Delayed feedback control: Stabilization of the period-five limit cycle. Time series for (a) the control signal, (b) the potential barrier. (Control is switched on at $t_c = 80$ ps; control parameters are $K = 0.1$ ps$^{-1}$ and $\tau = 17.05$ ps.) (c) Phase portrait of the stabilized period-five limit cycle. Transient processes are omitted.
Implementing this restriction in the physical system should be achieved by introducing some nonlinear electronic element in the feedback line so that the feedback signal reaches a saturation point at $D_0$. The effect of the restriction can be seen in Fig. 5 for the stabilization of the period-five limit cycle. Here the perturbation is small at all times, but the transient process is longer. The mean duration of the transient process increases with the decrease of $D_0$.

In general, unstable orbits are stabilized by the control only if $\tau$ and $K$ are chosen appropriately. For a systematic investigation we consider the variance $\langle D^2(t) \rangle$ of the control signal. When the system moves along a UPO, the amplitude of the feedback signal and hence $\langle D^2(t) \rangle$ is small. The variance $\langle D^2(t) \rangle$ has been determined as a function of the coupling constant $K$ for the two periodic orbits excluding transient processes in Figure 6. For both limit cycles a clear-cut interval for the value of $K$ can be observed in which stabilization can easily be achieved. In both cases this interval is fairly wide and begins at rather low values for the coupling constant.

To further investigate the range in which $K$ is suitable for stabilization of a given UPO, we have also calculated the largest non-zero Lyapunov exponent with respect to small deviations from the corresponding UPO. In Figure 7 the leading Lyapunov exponent $\lambda$ is plotted as a function of the coupling constant $K$ for the period-five limit cycle. For $K_{\text{min}} = 0.10 \text{ ps}^{-1} < K < K_{\text{max}} = 0.19 \text{ ps}^{-1}$, $\lambda(K)$ is negative, i.e. the UPO is stabilized. If $K$ is too small, the feedback is too weak for stabilization. If, on the other hand, $K$ is too large, the controlled variable $D(t)$ changes so rapidly that the other (uncontrolled) dynamical variables cannot follow fast enough. Note that negative $\lambda$ does not always imply that the UPO can be stabilized with a reasonably small control signal, as is evident from a comparison of Figs. 6(b) and 7.

When plotted as a function of the delay time $\tau$, the variance $\langle D^2(t) \rangle$ exhibits a typical resonance struc-

Fig. 7. The maximum non-negative Lyapunov exponent as a function of coupling constant $K$, calculated for the period-five limit cycle (delay time $\tau = 17.05$ ps). The arrows mark the absolute boundaries for stabilization.

4. Conclusion

We have demonstrated that Pyragas' method of delayed feedback control represents an efficient and easily realizable method to turn undesired chaotic behaviour in nonlinear semiconductor oscillators into a stable mode of operation, which can be tuned in discrete steps. By choosing an appropriate delay time of the control signal, corresponding to an integer multiple of the driving period, quite different modes of self-generated periodic oscillations can be conveniently selected. Such flexibility cannot be achieved with a linear electronic oscillator, and we suggest that the occurrence of chaos thus offers useful applications in the field of hot electron devices. The same method has also been applied to control magnetic-field induced chaos [19] in a model of low-temperature impurity impact ionization breakdown in bulk semiconductors [20]. Here we have elaborated these ideas for an oscillation mechanism applicable to modulation-doped semiconductor heterostructures, as proposed in [21]. From a practical viewpoint those semiconductor structures are much more flexible, and hence poten-
Fig. 8. Variance of the control amplitude as a function of delay time $\tau$, plotted for different initial conditions. Multistability occurs around $\tau = 17$ ps. The coupling constant is $K = 0.1$ ps$^{-1}$, perturbation is unrestricted.

Fig. 9. Same as in Fig. 8, but the control signal is restricted to $|D(t)| \leq D_0 = 0.1$. The branch of multistability at $\tau = 17$ ps has disappeared. Further resonance points can be seen at integer multiples of 10.23 ps and 17.05 ps, numbered in white and black, respectively.
tially useful, than bulk material. Finally we note that
the stabilization of UPOs can also give insight into the
dynamic structure of the uncontrolled chaotic system,
since the UPOs constitute the "building bricks" of the
chaotic attractor. The method of delayed feedback
control can also be used to stabilize a UPO in a
non-chaotic regime, and thus visualize, e.g., an un-
stable orbit which has appeared in a saddle-node bi-
furcation of two limit cycles.
